S. V. Maleev. Magnetic Dipole Forces and Dynamics of Critical Fluctuations Above the Curie Point in Ferromagnetics. Usually, only exchange forces are considered in studies of critical fluctuations in ferromagnets. This approximation is not adequate for description of the relaxation of homogeneous magnetization or the absorption of long-wave electromagnetic oscillations, since the exchange Hamiltonian conserves the total spin of the system. This conservation law is violated by magnetic interaction of atomic spins. The latter is anisotropic and long-range. Above the Curie point, this causes the spin Green's function to decompose into two parts, longitudinal and transverse with respect to the wave vector k. Because of the long-range action of the dipole forces at small k, these two parts are connected by the Krivoglaz relation

$$G = G_{\perp} \frac{1}{1 + \omega_0 G_{\perp}}, \quad \omega_0 = \frac{4\pi |\mu g|^2}{v_0},$$

with $\omega_0 G_{\perp} = 4\pi\chi$, where χ is the ordinary susceptibility. Near T_c , the susceptibility increases without limit, so that only the fluctuations perpendicular to the momentum k increase without limit in the temperature range where $4\pi\chi \gg 1$, and the parallel fluctuations are limited; but if $4\pi\chi \ll 1$, the fluctuations are isotropic. Thus, because of the long range of the dipole forces, there exists a temperature range (it might be called the dipole range) in which these forces, despite their smallness, cannot be considered in perturbation theory. As a result, the critical dynamics of the ferromagnet in the dipole range undergoes a radical change. A new characteristic momentum $q_0 = a^{-1} \sqrt{\omega_0 / T_c}$ at which G_{\parallel} and G_{\perp} become equal makes its appearance. For fluctuations with momentum larger than q_0 , there is the usual dynamic similarity with the same critical exponent $Z \approx 5/2$ as in the range $4\pi\chi \ll 1$. At the same time, a dynamic similarity regime with the new critical exponent $Z_d \approx 1$ appears for fluctuations with momentum k smaller than q_0 , and the characteristic energy of the critical fluctuations takes the form

$$\Gamma_k = T_c q_0^{3/2} \times f(k/\varkappa) \sim \begin{cases} T_c q_0^{3/2} \varkappa, & k \ll \varkappa, \\ T_c q_0^{3/2} k, & k \gg \varkappa, \end{cases}$$

where κ is the reciprocal radius of the critical fluctuations. Since $\kappa \sim \tau^{2/3}$ ($\tau = (T - T_C)/T_C$), as we should expect, the homogeneous relaxation time $t = \Gamma_0^{-1}$ increases without limit. In the range $4\pi\chi \ll 1$, the value of Γ_0 calculated from perturbation theory is then proportional to $\omega_0^2/T_C\tau$, so that the homogeneous relaxation time behaves nonmonotonically as τ decreases, reaching a minimum in the temperature range where $4\pi\chi \sim 1$.

O. M. Sumbaev, E. V. Petrovich, Yu. P. Smirnov, I. M. Band, and A. I. Smirnov. Use of a Method of Small X-Ray Line Shifts to Investigate the Electronic Structure of Crystal Chemical Bonds. An effect in which the energies of K-series x-ray emission lines vary with the chemical state of the emitting atom (a chemical shift) has been observed experimentally in the range of heavy elements (30 < Z < 75). It has been shown that the effect is directly related to the specific nature of the changes in the valence shells of the atom on formation of the chemical bond, and is explained by a mutual screening mechanism.

The general classification of experimental data on the chemical shifts (ΔE) of the K $_{\alpha 1}$ x-ray lines of the heavy elements (metals) in oxides or compounds with oxygengroup elements has been considered. It has been established that all of these experimental data, which cover more than 30 elements and 50 compounds, are described approximately by a relation of the type

$$\Delta E = i \sum_{l} m_{l} C_{l},$$

where i is the Pauling ionicity, $m = \sum_{l} m_{l}$ is the valence,

 m_l is the number of valence electrons with a given orbital quantum number l, and C_l is the energy change of the $K_{\alpha 1}$ line on complete removal of one valence electron of type l (s, p, d, f) from the atom, with $C_s = C_p \equiv C_{s,p} = 80 \pm 10 \text{ meV}, C_d = -115 \pm 10 \text{ meV},$ and $C_f = -570 \pm 30 \text{ meV}$ over the entire range of Z considered. The dependence of the effect on the distribution of the valence electrons over the l sublevels, i.e., on the valence configurations, and the differences in the signs and absolute values of the coefficients $C_{S,p}$, C_d , and C_f are alone sufficient to permit use of the effect as an experimental method of studying valence configurations. However, the scope of the method can be expanded by measuring the $K_{\alpha 1}$ shifts of both (electropositive and electronegative) partners in the compound and, most importantly, by using the other intense lines of the K series: $K_{\beta 1}$, 3 and $K_{\beta 2}$, 4. The experimentally measured shifts of the $K_{\alpha 1}$, $K_{\beta 1}$, and K_{32} 4 lines on stripping of s (p), d, or f electrons from the atoms are compared with theoretical calculations made within the framework of the Hartree-Fock-Slater method. Quite good agreement between the experimental and calculated shift vs. line-type relations is noted, especially in the case of 4f electrons. It is important that these relationships are found to be quite characteristic, differing for s(p), d, and f electrons and remaining unchanged in general outline in a broad range of Z (see figure). They serve as electron "facsimiles" of a sort, from which it is possible in a number of cases to judge with certainty which electron is involved in the phenomenon under study. If we compare the shapes of the experimental and calculated (experimental standard) "facsimiles," the ionicity is no longer needed, thus illustrating the advantages of the multiparameter (more precisely, three-parameter) character attained in the method. Study of the valence state of the formally bivalent thulium monochalcogenides TmTe, TmSe, and

Typical shift vs. line type $(K_{\alpha 1,2}, K_{\beta_{1,3}}, \text{and } K_{\beta_{2,4}})$ relations observed on removal (incorporation into an ionic chemical bond) of one s (p), d, or f electron and serving as "facsimiles" of valence electrons.
